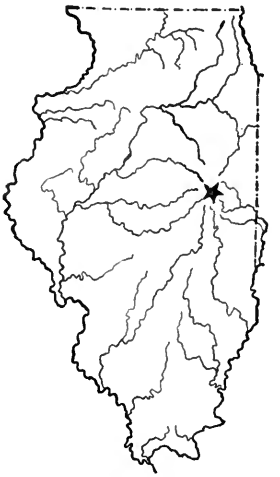
BULLETIN NO. 128

TEN GENERATIONS OF CORN BREEDING

By LOUIE H. SMITH



URBANA, ILLINOIS, SEPTEMBER, 1908

Summary of Bulletin No. 128

1. The results of ten years experiments in breeding corn to modify the composition of the grain and thereby adapting it to various special purposes are here reported.

2. Starting with a variety of average composition, it has been possible by selection and breeding, in ten generations: (1) to increase the average protein content from 10.92 to 14.26 percent; (2) to decrease the average protein content from 10.92 to 8.64 percent; (3) to increase the average oil content from 4.70 to 7.37 percent; (4) to decrease the average oil content from 4.70 to 2.66 percent. In other words, out of a single variety of corn two strains have been developed of which one is now almost twice as rich in protein as the other, and two other strains have been developed, one of which is now nearly three times as rich in oil as the other.
Page 468.

3. Variations among individual ears have been found ranging in protein content from 6.13 percent in the low-protein strain, to 17.79 percent in the high-protein strain, and in oil content from 1.60 percent in the low-oil strain to 8.59 percent in the high oil strain. Page 489.

4. Climatic conditions exert, in certain years, a marked effect upon the composition of the corn crop as regards its protein, oil, and starch content. Page 469.

5. Altering the composition of the grain has produced no very marked effect upon the composition of other parts of the corn plant. Page 476.

6. Continued selection appears to have induced a certain correlation between protein and oil content. Page 483.

7. Selection for the composition of the grain has resulted in characteristic types of kernel. Page 484.

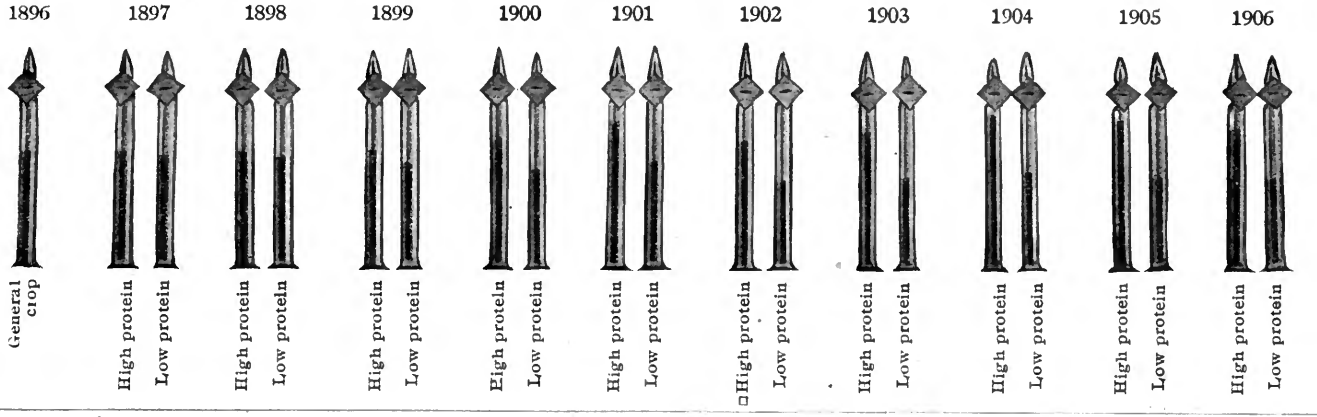
8. Perceptible modifications in the type of ear have likewise been wrought. Page 485.

9. Selection for high-protein is evidently accompanied by a reduction in yield. In the other strains the yields for the most part have been maintained in spite of the rigorous selection for the special chemical characteristics. Page 485.

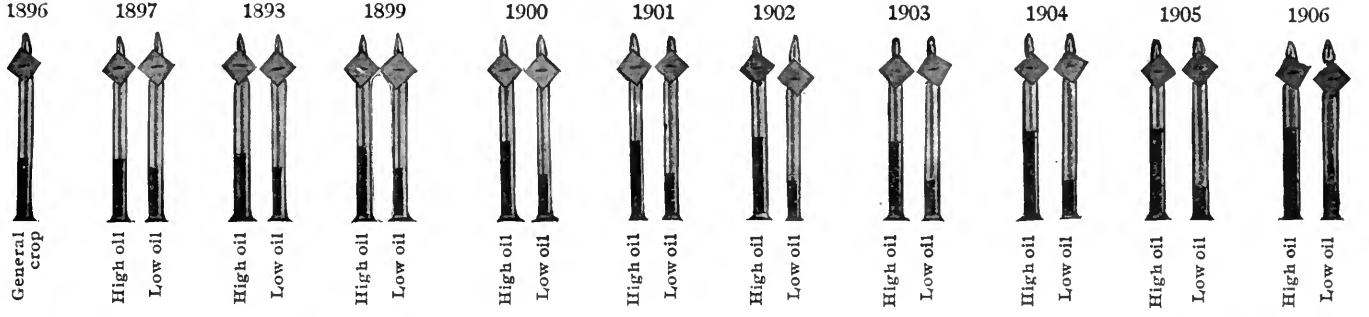
10. The detailed plot records of each of the four strains and the analytical results of nearly 5000 individual ears which have been analyzed during the ten years' work are placed on record in the appendix to this bulletin in such arrangement that the maternal pedigree record of every ear is shown. Page 490.

11. These four breeding plots are still being continued.

PHOTOGRAPH I. TEN YEARS CORN BREEDING FOR HIGH AND LOW PROTEIN



PHOTOGRAPH II. TEN YEARS CORN BREEDING FOR HIGH AND LOW OIL



Photograph I illustrates the results of breeding corn for increase and decrease of protein content; Photograph II, for increase and decrease of oil content. The bottles show the amount of protein or oil contained in one-tenth bushel of corn from the crop of the different strains each season for the first ten generations.

INTRODUCTORY NOTE

By Cyril G. Hopkins, Chief in Agronomy

In 1896 the Illinois Experiment Station began the improvement of corn by varying the composition of the grain through selection and breeding. The results of the first two years of these investigations were published in Bulletin No. 55 "Improvement in the Chemical Composition of the Corn Kernel." This same work has been carried on continuously since that time, and although several publications have been issued in the meantime bearing upon different phases of the subject of corn improvement as it has been developed, including Bulletins 82, 87, 100, and 119, there has, however, been no complete report published of the results obtained in the progress of this original line of work described in Bulletin No. 55.

It is the present purpose therefore to present the results which have been obtained, in the first ten generations, in improvement in composition in various directions, namely, for high protein, for low protein, for high oil and for low oil, of the single variety of corn from which these four different strains have been produced, and which is known as "Illinois" corn.

Since the discovery of the possibility of improving corn for special adaptation and the general recognition of its importance, this Station has extended its work to other standard varieties of corn best adapted to different sections of the state, applying the methods and principles worked out in the original experiments with the "Illinois" variety. This work of improving the other standard varieties both for yield and for special adaptation is being carried on largely in co-operation with seed corn breeders of the state. A large amount of data relating to this later work has already accumulated, but it is proposed to reserve this for future publication rather than to attempt to cover in this report all of the corn breeding work now in progress believing that such a division of the subject will allow a clearer presentation.

Inasmuch as the editions of Bulletins 53 and 55 are already exhausted and the demand for the information contained therein is still unsatisfied, it is proposed to make the nature of this report as complete a presentation of the investigation as is possible without making too great repetition of material already published.

For several years Professor Louie H. Smith has been largely responsible for the conduct of these investigations, valuable assistance having also been rendered during recent years by Doctor E. M. East, now agronomist at the Connecticut Experiment Station, Mr. R. W. Stark, now chief chemist for the Cuban Experiment Station, Mr. H. H. Love, and Mr. C. H. Myers.

TEN GENERATIONS OF CORN BREEDING

By LOUIE H. SMITH, Assistant Chief in Plant Breeding

IMPORTANCE OF CORN IMPROVEMENT

Aside from the purely scientific interest attached to this work, the practical importance of improvement of corn to adapt it for special purposes as well as for increased yield is now becoming generally recognized. The significance of improving the chemical composition of corn has already been pointed out in Bulletins 55, 82, 87, and 100 of the Illinois Experiment Station, and it is scarcely necessary to dwell upon this phase of the subject further than to refer briefly to some of the demands for corn improved along these particular lines.

No other crop is made to serve such a variety of purposes as corn, and in consideration of these many different uses is suggested the question of special adaptation.

Purpose of increasing the protein.—In the nutrition of man and beast protein is the most expensive nutrient. Of all of our American food stuffs corn is the cheapest, because of its economical production. But because corn does not contain sufficient protein for most purposes of feeding, it must be re-inforced by other more expensive food stuffs in order to obtain the proper ratio of this important nutrient. It is from these considerations that farmers, and especially stock feeders, recognize the importance of breeding corn for increase of protein content.

Purpose of decreasing the protein.—On the other hand, there is a demand from the manufacturers of those products which are derived from the starch of corn such as glucose, gum, dextrine, syrup, and alcohol, for a corn having a large proportion of carbohydrates and not so rich in protein. The practical effect of decreasing the percent of protein is to increase the percent of starch; therefore, for such purposes there should be a place on the market for corn which is bred for decrease of protein content.

Purpose of increasing the oil.—The oil of corn has in recent years found such a wide commercial use that under the present market conditions, it has become, pound for pound, by far the most valuable constituent of the grain, and whereas formerly in the glucose factories and corn mills the germs containing the oil were

almost a waste product, there is now an actual demand on the part of these industries for corn which is richer in oil. It is proposed to meet this demand by breeding corn for increase of oil content.

Purpose of decreasing the oil.—There is also a practical use for corn with a low oil content. It has been found by investigation that in feeding swine, the oil in the corn tends to produce a soft, flabby quality of flesh which is very undesirable, especially for our export trade where the demand of the market is for a hard, firm product. A remedy for this lies in the reduction of the oil content of the corn which is fed. Thus here we have a very important practical object for breeding corn for decrease of oil content.

These special purposes mentioned for which corn is being improved suggest the possibility of many others demanded by the various industries which utilize the corn crop and which require different qualities in it.

Corn improvement should, of course, embrace quantity as well as quality and in all practical work of selection looking toward improvement, the matter of increased yield per acre should be given first consideration. Recognizing the importance of this principle, the methods used in these experiments have been chosen with the view of maintaining or increasing the yield, and productiveness is made the basis of the first selection, even sometimes at a sacrifice in percentage of the desired chemical constituent.

FUNDAMENTAL PRINCIPLES

Before taking up this work of the improvement of corn by systematic selection and breeding, it was necessary to make a preliminary study of the subject such as is reported by Doctor Hopkins in Bulletin 53 "Chemistry of the Corn Kernel." In this study a large amount of valuable knowledge was gained which bears upon the technical side of the work, such as the chemical principles involved and the laboratory manipulations upon which the success of the entire work so intimately depends. Further, important data were obtained from which were derived the principles of selection upon which all of this work in improvement of the composition of corn is based. All improvement by selection and breeding depends, of course, upon variation, therefore it was necessary to make a preliminary study in order to learn how corn varies with respect to its composition. As the result of such an investigation the following data were obtained:

Analysis of parts of the ear.—In studying this question 30 duplicate analyses were first made on different parts of ears. Five ears were divided lengthwise into 3 samples each in the following

manner: If the ears were 12-rowed, 3 samples of 4 consecutive rows each were made; if 16-rowed, 3 samples of 5 consecutive rows each were made, one row being left, etc., etc.

Duplicate analyses of 15 samples thus prepared from 5 different ears gave the results shown in Table 1. The different ears are distinguished by the letters (a), (b), (c), (d), and (e).

TABLE 1.—VARIATION IN COMPOSITION IN SAMPLES FROM THE SAME EAR AND FROM DIFFERENT EARS

Sample & Ear.	Ash.	Protein.	Oil.	Carbohydrates.
1 (a)	1.42	10.79	4.57	83.22
	1.43	10.75	4.58	83 24
2 (a)	1.48	10.97	4.54	83.01
	1.47	10.94	4.51	83.08
3 (a)	1.50	10.66	4.53	83.31
	1.51	10.72	4.55	83.22
4 (b)	1.51	12.00	4.60	81.89
	1.52	11.98	4.59	81.91
5 (b)	1.49	12.01	4.57	81.93
	1.48	12.05	4.57	81.90
6 (b)	1.48	12.19	4.85	81.48
	1.47	12 08	4.80	81.65
7 (c)	1.37	10.09	5.24	83.30
	1.37	10.10	5.17	83.36
8 (c)	1.31	10.14	5.08	83.47
	1.34	10.18	5.18	83.30
9 (c)	1.36	10.15	5.20	83.29
	1.37	10.20	5.17	83.26
10 (d)	1.39	10.46	4.28	83.87
	1.38	10.46	4.29	83.87
11 (d)	1.43	10.25	4.22	84.10
	1 42	10.27	4.20	84.11
12 (d)	1.43	10.09	4.16	84.32
	1.45	10.06	4.15	84.34
13 (e)	1.34	11 19	4.80	82.67
	1.36	11.20	4.78	82.66
14 (e)	1.30	10.66	4.91	83.13
	1.28	10 62	4.89	83.21
15 (e)	1.36	10.81	4.83	83.00
	1.36	10.92	4.79	82.93

These results indicate uniformity in the composition of different parts of the ear. The following shows the greatest total variation in the 6 single determinations of each constituent in any one ear; and also the total variation between the different ears.

	Ash.	Protein.	Oil.	Carbohydrates.
In any single ear.	.09	.58	.28	.55
In five ears.....	.24	2.13	1.09	2.86

Another lot of five ears was selected and each of these was divided crosswise into 3 samples of approximately equal amounts, which for convenience are designated "tip," "middle" and "butt," the ears being lettered (f), (g), (h), (i) and (j). The results of the duplicate analyses are given in Table 2.

It is observed that in every case the tip is the lowest in protein and that usually the middle is lower than the butt, the average total difference in the ear being 0.73 percent and the widest 1.13 percent as shown in the total variations following Table 2.

The variation in ash and oil is small and shows no such peculiarity. The carbohydrates, being determined by difference, appear, of course, as the complement to the sum of the other substances and show in the opposite direction approximately the variation of the most variable determinable constituent.

Partial analyses of ***single*** *kernels.*—For the work on ash content several ears of corn were selected, and from each a sample of corn, consisting of a number of rows of kernels and believed to fairly represent the ear, was taken and its percentage of ash in the dry matter determined. Then for special investigation of ash content of single kernels four ears from the lot were chosen, of which two were high and two low, comparatively, in percentage of ash as previously determined. From each ear 10 kernels were selected at approximately equal distance throughout the length of the ear, the kernels being numbered from 1 to 10 and the order running from tip to butt. The data from the ash determination in single kernels and also percentage of ash in the large sample from the same ear are given in Table 3.

TABLE 2.—VARIATION IN COMPOSITION IN BUTT, MIDDLE AND TIP PORTIONS OF THE SAME EAR AND OF DIFFERENT EARS

Sample & Ear.	Ash.	Protein.	Oil.	Carbohydrates.
16 (f)	1.58	11.78	5.09	81.55
Tip	1.59	11.76	5.10	81.55
17 (f)	1.58	12.22	5.13	81.07
Middle	1.57	12.26	5.03	81.14
18 (f)	1.56	12.36	5.04	81.04
Butt	1.58	12.42	5.03	80.97
19 (g)	1.49	11.99	4.86	81.66
Tip	1.49	11.97	4.84	81.70
20 (g)	1.51	12.49	4.77	81.23
Middle	1.51	12.49	4.76	81.24
21 (g)	1.50	13.02	4.57	80.91
Butt	1.51	13.10	4.59	80.80
22 (h)	1.37	9.72	3.90	85.01
Tip	1.35	9.67	3.93	85.05
23 (h)	1.37	10 07	3.98	84.58
Middle	1.35	10.08	3.97	84.60
24 (h)	1.51	10.49	4.01	83.99
Butt	1.49	10.46	4.00	84.05
25 (i)	1.47	10.58	4.58	83.37
Tip	1.48	10.61	4.60	83.31
26 (i)	1.45	11.05	4.56	82.96
Middle	1.44	11.03	4.60	82.93
27 (i)	1.47	11.03	4.48	83.02
Butt	1.48	10.96	4.46	83.10
28 (j)	1.77	10.87	4.36	83.00
Tip	1.74	10.78	4.37	83.11
29 (j)	1.65	11.35	4.56	82.44
Middle	1.62	11.31	4.58	82.49
30 (j)	1.71	11.32	4.28	82.69
Butt	1.72	11.28	4.29	82.71

The following shows the total variation:

	Ash.	Protein.	Oil.	Carbohydrates.
In any single ear....	.16	1 13	.30	1.06
In five ears.....	.42	3.43	1.23	4.25

TABLE 3.—VARIATION IN ASH CONTENT IN KERNELS FROM THE SAME EAR AND FROM DIFFERENT EARS

Kernel No.	Ear No. 1	Ear No. 2	Ear No. 3	Ear No. 4
1	1.50	1.64	1.10	1.14
2	1.57	1.64	1.08	1.23
3	1.61	1.63	1.09	1.13
4	1.56	1.65	1.10	1.17
5	1.67	1.59	1.07	1.13
6	1.69	1.63	1.09	1.22
7	1.71	1.68	1 07	1.25
8	1.64	1.65	1.10	1.19
9	1.64	1.70	1.21	1.11
10	1.74	1.60	1.11	1.10
Composite of ear	1.73	1.65	1.10	1.11

These results confirm those of the previous experiments in indicating uniformity in the composition of the ear in all parts, although, of course, slight variations are found.

In the work on the protein content of single kernels, 5 ears, 3 of which were high and 2 relatively low in protein, were selected from a number of ears in a manner analogous to that described in the previous experiment. In Table 4 are shown the results of these protein determinations.

TABLE 4.—VARIATION IN PROTEIN CONTENT IN KERNELS FROM THE SAME EAR AND FROM DIFFERENT EARS

Kernel No.	Ear No. 1	Ear No. 2	Ear No. 3	Ear No. 4	Ear No. 5
1	12.46	12.17	11.53	7.45	7.72
2	12.54	12.94	12.32	7.54	8.41
3	12.44	12.51	12.19	7.69	8.37
4	12.50	13.42	12.54	7.47	8.31
5	12.30	13.12	12.14	7.74	8.02
6	12.49	14.59	12.95	8.70	8.76
7	12.50	13.21	12.84	8.46	8.89
8	12.14	13 43	.....	8.69	9.02
9	12.14	13.16	12.04	8.86	8.96
10	12.71	14.05	12.75	8.10	8.89
Composite of ear	13.06	13.87	12.96	7.59	8.40

Here in the protein content, as in the case of the ash, we find on the one hand comparative uniformity among different kernels of a single ear and on the other, marked variation among different individual ears.

The results of these analyses of different ears from a single variety together with analyses of different parts of single ears establish beyond question two important fundamental facts upon which all of this subsequent work of selection and breeding is founded.

The statement of these facts is as follows:

(1) *The ear of corn is approximately uniform throughout in the chemical composition of its kernels.*

(2) *There is a wide variation in the chemical composition of different ears of the same variety of corn.*

With these two principles established, we have a working basis for the chemical selection of seed corn. With uniformity in the individual ear, it is possible to determine very approximately the composition of the grain by analyzing a sample consisting of a few rows of kernels, and this is the actual practice in the examination of individual ears. If the ear represented by this sample is found to be desirable for seed, the remainder of the kernels of the ear may then be planted.

The wide variation in composition between different ears of the same variety is a very important factor in the selection of seed; as a starting point is thus furnished in each of the several lines of desired improvement.

It is to be observed that this principle of uniformity within the individual, and variation as between different individuals within the variety, holds not only for the chemical composition of the kernel but it applies as well to other characteristics such as the structure, for example, and whenever any such characteristic is related to productiveness or other utility of the crop, it should be taken into account in the breeding.

GENERAL PLAN OF THE EXPERIMENTS

In the general plan of these experiments, it was proposed to determine the influence upon the chemical composition of corn by selection and breeding in the four directions namely, (1) for increase of protein content, (2) for decrease of protein content, (3) for increase of oil content, (4) for decrease of oil content.

The method employed was as follows:

For the first selection a large number of ears were analyzed both for protein and for oil. In the high protein breeding, for example, the 24 ears highest in protein were selected for seed and planted in a plot isolated from other sorts of corn, each ear in a separate row.

These rows were harvested separately and the seed for the next planting was selected from ears of this crop which were found to be highest in protein, repeating this process each year. The breeding for low protein and for high oil and low oil was conducted on the same plan. Under this system each selection rapidly gave rise to a "pure" strain. As each original ear had its own register number and as all succeeding ears bore corresponding numbers the exact pedigree of each row (on the female side) was at all times fully known.

This general method has been maintained from the beginning, although some minor modifications of details have been made from time to time during the progress of the work as experience indicated as being desirable or as necessity demanded.

THE BREEDING PLOT

The size of the breeding plot has varied in the different plots and in the different years. The number of rows included in any plot is always given in the plot records.

The locations of these breeding plots have always been chosen with reference to their isolation from other corn fields in order to prevent cross fertilization from other kinds of corn. It is quite difficult with so many corn experiments as are carried on at this Experiment Station to obtain conditions that are ideal in this respect, but by taking advantage of tall hedge rows, and other barriers, prevailing winds, and other corn fields of the same strain, there has been but slight, if any, admixture in these breeding plots. A system of alternating the locations of the breeding plots of the opposite strains has been carried out. For example, after the first two years the locations of the high-protein and the low-protein plots were reversed; that is the high-protein plot was planted on the same ground that the low-protein plot had occupied the two preceding years and *vice versa*. After two years more these plots were shifted back to their original locations. The high-oil and low-oil plots were managed in the same manner. The design of this alternation of location of the plots was to provide something of a check upon the possible influence of soil upon the composition

of the crops. The plots have been changed to other locations in later years but this system of alternating has been maintained. For each of these breeding plots there is now provided a double area which makes possible a crop rotation system including clover and other legumes, for maintaining the productivity of the land.

CULTURAL CONDITIONS

The cultural methods, including the preparation and cultivation of the soil, planting, harvesting, and handling of the crop on these breeding plots have been such as is considered good practice in ordinary corn growing. The seed has always been planted in hills in preference to drills. The present practice is to plant the hills three feet apart each way and to allow two stalks to the hill.

Attention is paid to the matter of preventing the distribution of pollen from weak, barren or otherwise undesirable plants by detasseling all such plants at the proper time.

After discovering the great advantage to be gained by the method of detasseling alternate rows and taking seed only from such detasseled rows, as pointed out in Bulletin 100, this system has been applied to all of our regular breeding plots.

The method of harvesting has been that of cutting and curing in the shock.

SAMPLING AND SELECTING

In the earlier years of the experiments a sample from each of all of the rows was reserved by selecting a certain number of the choicest ears as judged from their physical appearance. But as the possibility of improvement became more clearly established, a system was adopted by which seed ears for the next year's planting are taken only from those rows which prove to be most productive as determined by the weight of ear corn produced, all other rows of the plot being rejected as a source of seed, and since the introduction of the system of detasseling alternate rows, only the best of the detasseled or "dam" rows have been selected. This method of selecting the choicest ears to represent the plot-row has been followed throughout the work although details of the system as regards the number of ears taken have been somewhat modified in the different years, as will appear in connection with the data which follow in the appendix.

The ears, thus chosen on account of their physical superiority, are then subjected to chemical analysis and from the results of these analyses is made the final selection of seed for the succeeding season.

In the sampling for these analyses two rows of kernels are taken lengthwise of the ear to represent the composition of the individual ear. At the same time composite samples to represent the selected plot-rows are taken by mixing together one row of kernels from each selected ear of the respective plot-rows. Each seed ear thus selected is given a permanent "Register Number" which designates that ear for all future reference.

REGISTERING

By our system of numbering the "Register Number" shows at the same time the number of the ear and the generation of the breeding. This is done by starting the first year in the 100 series numbering the ears to be planted in succession from 101, and the second generation starting with the 200 series running up from 201 and so on, starting each succeeding year of the breeding with a higher hundred. Thus Ear No. 1018 shows that this ear belongs to the tenth generation and was planted in row 18 of the breeding plot of that year. The "Dam No." is the register number of the parent ear and is useful in tracing the pedigree record from year to year. The "Annual Ear No." is simply a temporary number given to each ear to be used during examination for selection and as soon as the selection of the seed ears has been determined and the arrangement for planting has been decided the ears are given their permanent register numbers.

A description of the physical as well as the chemical characteristics of all the seed ears is kept on record including length of ear, tip circumference of ear, butt circumference of ear, number of rows of kernels, number of kernels in row, weight of ear, weight of cob, tip circumference of cob, and butt circumference of cob. Besides this numerical description a photograph record is also kept of every ear planted.

The performance record of each seed ear is shown by the weight and number of ears produced as well as the average composition of its progeny.

For a more detailed description of the system of registry used in our corn breeding work the reader is referred to Bulletin 100.

VARIETY

The variety of corn selected for this investigation was one of medium size and of safe maturity for this latitude. It has been grown upon the Experiment Station farm every year since 1887. Previous to that time it had been carefully grown for several years

by Mr. F. E. Burr of Champaign county, and it was known locally as Burr's White; and this name was used in our records until 1903, when it was decided to change the name to "Illinois." The fact that these strains of corn are no longer typical Burr's White, and the fact that this corn was carefully grown for several years prior to 1896 by the Illinois Experiment Station and that since that time it has been most carefully bred by this Station for improvement in both yield and quality, so that there have been developed from this variety four different strains of corn each of which has an established pedigree now covering ten generations,—these facts have seemed to justify giving this corn a name which shall be distinctive and which shall also show its Illinois breeding; and now it is known in the records and publications of the Illinois Experiment Station as "Illinois" corn, the four different strains being designated as:

1. "Illinois High-Protein."
2. "Illinois Low-Protein."
3. "Illinois High-Oil."
4. "Illinois Low-Oil."

FIRST SELECTION OF SEED

From the 1896 crop of Burr's White corn grown upon the Experiment Station farm about two bushels (163 ears) of good sound ear corn suitable for seed were taken. From each ear a sample consisting of three rows of kernels lengthwise of the ear was taken for analysis. The results of these analyses are given in the first table of the appendix (Table 15). The data obtained show remarkable variation in the relative proportions of the different constituents. The ash varies from 1.10 to 1.74 percent, the protein from 8.25 to 13.87 percent, the oil from 3.84 to 6.02 percent and the carbohydrates from 78.92 to 85.70 percent. This is a good illustration of the variation in composition existing among individual ears of the same variety and indicates something of the possibilities for selection.

According to these variations there were taken from the 163 ears four groups,—(1) a set of twenty-four ears whose percentage of protein was comparatively high, (2) a set of twelve ears each of which contained a low percentage of protein, (3) a set of twenty-four ears high in oil content, (4) a set of twelve ears low in oil content.

These ears were taken as indicated in the last two columns of Table 15, for the seed with which to start the four respective breeding plots.

It is believed that the interest in this investigation is such as to demand the publication of a complete record of the results in detail, but this data forms such a mass of material as to make it seem advisable to place it in an appendix to this bulletin and to summarize here only the yearly averages which show very well the general results of the work. The reader who may be interested in further detail of the experiments at any point is therefore referred to the appendix (pages 489 to 575) where will be found the complete data recorded in systematic arrangement. (If not attached to this copy, the appendix will be sent upon request).

BREEDING TO INFLUENCE THE PROTEIN CONTENT

In order to obtain a general survey of these experiments to influence the protein content of corn the following table is compiled from the general averages obtained each generation from the corresponding tables given in the appendix:

TABLE 5.—TEN GENERATIONS OF BREEDING CORN FOR INCREASE AND DECREASE OF PROTEIN

Year	High-protein plot, average percent protein.		Low-protein plot, average percent protein.		Difference between crops, percent.
	In seed planted.	In crop harvested.	In seed planted.	In crop harvested.	
1896	.....	10.92	....	10.92	.00
1897	12.54	11.10	8.96	10.55	.55
1898	12.49	11.05	9.06	10.55	.50
1899	13.06	11.46	8.45	9.86	1.60
1900	13.74	12.32	8.08	9.34	2 98
1901	14.78	14 12	7.58	10.04	4.08
1902	15.39	12.34	8.15	8.22	4.12
1903	14.30	13.04	6.93	8.62	4.42
1904	15.39	15.03	7.00	9.27	5.76
1905	16.77	14.72	7.09	8.57	6.15
1906	16.30	14.26	7.21	8.64	5.62

From this arrangement of the data we may compare the results of the different seasons and at the same time observe the relations between the two plots, thereby enabling us to follow the progress of the breeding from year to year.

Starting with the crop of 1896 with an average protein content of 10.92 percent, as represented by the original 163 ears, the average of the seed ears selected for the high-protein plot of 1897 was 12.54 percent while at the same time low-protein seed ears were

selected which averaged 8.96 percent. The crop harvested from the high-protein plot in 1897 gave an average of 11.10 percent of protein while the average of the corresponding low-protein plot was 10.55 percent. Then selecting again the highest-protein ears out of this year's crop from the high-protein plot, seed for the following year was obtained which averaged 12.49 percent. Selecting the lowest protein ears from the low-protein plot, the seed for this plot in 1898 averaged 9.06 percent.

Repeating this process each year the effect has been in a general way to gradually increase or decrease the protein content in the corn according to the selection.

In glancing over the records there are a few irregularities to be seen. Comparing the results of the season of 1898 with that of the preceding year we seem to have lost a little ground in the high-protein breeding, and in the low-protein plot there was no advance made.

The next year however, following a more favorable seed selection in each case, good gains were made in both directions in 1899, and the same is true of the year 1900.

In 1901 the results are abnormal and here we have a striking illustration of the effect which may be produced by the climatic conditions of the season upon the composition of the crop. This year the protein rises abnormally high in the high-protein crop gaining 1.8 percent over that of the year before and in the low-protein crop, instead of getting the expected decrease this year the protein content rises to over ten percent, thus reverting back to a point higher than it had been for two generations. The season of 1901 was an extremely dry one and from the lack of sufficient moisture much of the corn did not properly "fill out." In the formation of the kernel the proportion of protein is greatest in the younger stages of growth and this proportion gradually diminishes as the carbohydrates are deposited. If the conditions are such that this deposition of carbohydrates is checked, as they were this season, the corn comes to maturity with an abnormally large proportion of protein.

In the case of the high-protein plot the damaging effect of this drouth was so pronounced as to render the crop almost a total failure. The yield of ear corn amounted to only about six bushels per acre and consisted mostly of mere nubbins. On account of the scarcity of ears, it was impossible to follow the regular system of sampling, so the entire product from each plot-row was collected and all of the sound ears and even many nubbins were selected for

analysis in order to obtain the results of the year and to get any sort of seed with which to maintain the experiment. The composite samples representing the high-protein crop are therefore not obtained from the best twenty ears from each plot-row according to the regular system but they were taken from all of the corn fit to analyze from each row. Thus there were altogether only 60 individual ears from which only five were chosen for seed as being fit to plant. Fortunately it was possible to supplement these with some seed ears from our "Special High-protein" plot which was being carried on for another experiment but which was planted from the same strain as the regular high-protein plot so that these ears could be substituted without disturbing the pedigree record. The low-protein plot did not suffer so badly from the drouth, so that here the sampling and selection were made as usual.

During the season of 1902 the climatic conditions as regards rainfall were just the opposite to those of the previous year and we observe in the results obtained precisely the opposite effect. With the very wet season this year we have a great diminution of protein content in the corn in the high-protein as well as in the low-protein plot.

This seasonal condition which seems to have such a marked influence upon the composition of the corn is quite significant. The season of 1901 was very dry and it was attended by an abnormally high protein content in all the corn examined that year. The season of 1902 was unusually wet and the general tendency was to produce corn low in protein. These results are in accordance with those of other investigations, particularly in irrigation experiments where it has been observed that the quantity of water supplied has a direct influence upon the composition of corn, wheat, and oats, the protein content of the grain decreasing as the water supply increases. These results support what seems to be a general principle namely, that a lack of moisture tends to increase the proportion of protein and abundance of moisture reduces it, due, of course, to the effect of water supply upon carbohydrate formation.

With a fairly normal season in 1903 the high-protein crop made a notable advance, but the low-protein in spite of the extremely low content of the seed this year did not go down to the point attained in the low-protein season of the previous year, and in fact we have never been able since to bring it back to the extremely low point reached that year.

The season of 1904 appears to have been another one favorable to the production of protein, for the high-protein plot made a gain

of two percent this year and reached its maximum figure, 15.03 percent, a point which has not since been attained. The low-protein plot shows a similar effect, for instead of decreasing this year, it goes up to 9.27 the highest average percentage in the last five generations of the breeding.

In 1905 as might be expected the content in the high-protein crop was not so high as in the preceding high-protein season. In the low-protein plot a good gain was made this year for low-protein.

In 1906 the percentage in the high-protein was still lower than in 1905 while in the low-protein crop, the percentage was a little higher than in the year before although the difference is not great.

The figures in the last column of the table showing the difference between the percentages of protein in the two crops produced each year are perhaps most instructive because they show the real progress attained in the breeding. They enable us to appreciate more fully the scientific value of breeding for high protein and low protein simultaneously and thereby obtaining a control upon the work which serves to eliminate the question as to the effect of seasonal tendencies in either direction.

These figures practically show a continuously increasing separation between the high-protein and the low-protein strains as the breeding advances up to 1906 so that with the exception of two slight regressions, whether the tendency of the season has been toward the production of high-protein corn or low-protein corn, the force of an hereditary influence is demonstrated always to have been in operation.

It is to be recognized of course that there are practical limits both maximum and minimum to which this matter can be carried and we should expect to finally reach a state where we would interfere with the normal physiological functions of the seed.

As to whether this last year's result in which no more gain was made in the difference between the high and low, is to be taken as indicating that we have reached these limits cannot yet be positively decided. It seems scarcely probable that with seed still unimpaired in vitality and developing into normal healthy plants furnishing otherwise normal crops that the ultimate limits should be at hand. It is proposed still to keep up the selection along these lines and the outcome of the next few years will be awaited with interest.

The results of these experiments thus far show that starting with a single variety of corn, it has been possible in ten generations

by these methods of selection and breeding to increase the protein content from 10.92 percent in the original to 14.26 percent, thus making a gain of 3.34 percent, and at the same time by breeding in the opposite direction it has been possible to reduce the protein content from 10.92 percent to 8.64 percent, making a reduction of 2.28 percent, thus producing a total difference between the two strains of 5.62 percent. In other words the composition of this variety of corn has been so modified that two strains have been developed, one of which is now nearly twice as rich in protein as the other.

MIXED-PROTEIN PLOT

In order to eliminate the question as to whatever influence the soil might exert on the protein content of the corn an experiment was undertaken in which high-protein and low-protein seed were planted together in one plot, our so-called "Mixed-Protein Plot," where the two strains must develop under identical surrounding conditions.

The description and results of the first year of this experiment are given in Bulletin 55. The first year this mixed-protein plot contained five rows of ten hills each. In each hill were planted two kernels of high-protein corn on one side and two kernels of low-protein on the opposite side in such manner that the resulting plants could be identified.

When the crop was harvested eight to ten ears were selected from each kind of corn from each row and from these ears composite samples were made for analysis. These analyses showed that the average protein content of the corn from the high-protein seed was invariably higher than in that produced from the low-protein seed.

This same experiment was repeated in a somewhat larger plot in 1899 and also in 1900. (See Tables 96, 97 and 98 in the appendix for details).

The differences in protein content between the crops from high-protein and low-protein seed were 1.25 percent in 1898, 2.58 percent in 1899, and 2.86 percent in 1900.

Besides these composite samples there were analyzed from the mixed-protein plot of 1899, 137 pairs of ears in which each pair consisted of an ear produced from a high-protein kernel and one from a low-protein kernel and growing together in the same hill. The results of these analyses are given in Table 99 of the appendix and they show an average difference of 2.58 percent to be attributed positively to the influence of the seed selection. But with still further interest, it is to be noted that among these 137 different

pairs, there are only ten cases in which the higher percentage of protein is not found in the ear produced from the high-protein kernel. The most notable of these exceptions occurs in case of Row No. 2, Hill No. 11 where the low-protein kernel produced an ear 3.73 percent higher in protein than the ear resulting from the high-protein kernel. However, these abnormal individual variations are to be expected and they have frequently been observed throughout all of these experiments.

The results of these experiments with the mixed-protein plots during these three different years establish beyond question the fact that the protein content of the corn crop is influenced directly by the seed planted, independently of soil, seasonal, or cultural conditions.

BREEDING TO INFLUENCE THE OIL CONTENT

Summarizing the results of the ten generations of breeding to influence the oil content in the same manner as we have considered the protein breeding, there are brought together from the detailed records in the appendix the general yearly averages of the high-oil and low-oil plots as arranged in Table 6.

TABLE 6.—TEN GENERATIONS OF BREEDING CORN FOR INCREASE AND DECREASE OF OIL

Year.	High-oil plot, average percent oil.		Low-oil plot, average percent oil.		Difference between crops, percent.
	In seed planted.	In crop harvested.	In seed planted.	In crop harvested.	
1896	....	4.70	....	4.70	.00
1897	5.39	4.73	4.03	4.06	.67
1898	5.20	5.15	3.65	3.99	1.16
1899	6.15	5.64	3.47	3.82	1.82
1900	6.30	6.12	3.33	3.57	2.55
1901	6.77	6.09	2.93	3.43	2.66
1902	6.95	6.41	3.00	3.02	3.39
1903	6.73	6.50	2.62	2.97	3.53
1904	7.16	6.97	2.80	2.89	4.08
1905	7.88	7.29	2.67	2.58	4.71
1906	7.86	7.37	2.20	2.66	4.71

The results show that the response to selection for oil has been even more pronounced and more regular than that for protein as indicated by the total relative increase and decrease and by the changes from year to year.

In the percentages representing the crop produced each year in the high-oil plot there has been with but one exception, namely, in

1901, a constant increase in oil content as the breeding proceeds. Likewise in the low-oil plot there has been a steady decrease from year to year with the single exception of the last year.

We have noted the marked effect which the abundance or scarcity of moisture may have upon the protein content of corn, and in these experiments the oil content appears also to be susceptible to some peculiar seasonal conditions. What these conditions are have not been determined, but that they exist is made apparent if we compare the increase and decrease in the percentage of oil in each generation in the two plots. It would appear as though certain seasons were particularly favorable to the production of oil, while other seasons may be normal or unfavorable in this respect. This effect is particularly apparent in the first two years of the breeding; thus, the season of 1897 seems to have been very unfavorable, while the season of 1898 appears to have been very favorable, to the production of oil.

From the last column in the table which shows, by the differences in percentage between the high-oil and the low-oil crops each year, the real progress accomplished by the breeding, we see that there has been a continuously increasing difference between the percentages of oil in the corn from the two plots up to the tenth year where this difference remains stationary. The high-oil corn has increased from 4.70 percent to 7.37 percent of oil, and the low-oil corn has decreased from 4.70 to 2.66 percent, the difference between the two strains having grown from nothing in 1896 to 4.71 percent in 1905. Curiously enough the oil breeding resembles the protein in the fact that there is constant progress indicated until the tenth year when in each case this progression ceases. In the protein experiments it will be recalled that the figures in this "difference column" show actually a slight regression in the tenth year while here in the oil breeding the differences between the averages of the high-oil and low-oil crop stands exactly stationary in the last two years.

As has already been remarked in the discussion of the protein breeding results, it would be rash to decide at this time from these figures that the limits to which the breeding can be carried are now determined.

Summarizing the results of the ten years' experiments to influence the oil content into one general statement we may say that starting with a single variety of corn and breeding in the two opposite directions, there has been a constantly widening separation between the two strains as the breeding advances until finally after ten generations there have been produced two kinds of corn, one of which is almost three times as rich in oil as the other.

MIXED-OIL PLOT

In order to eliminate any question of the influence of the soil upon the oil content in these experiments, a third plot was planted called the "mixed-oil plot," after the plan of the "mixed-protein plot" already described under that heading. In 1898 there were planted in this plot 50 hills arranged in five rows of ten hills each. In each hill two kernels of high-oil corn were planted on one side and two of low-oil on the opposite side and when the crop was harvested composite samples were made to represent the corn of each side of the row.

This same experiment was repeated in 1899 and also in 1900 the details being given in Tables 100, 101 and 102 of the appendix.

From the results it is to be noticed that never in any of the rows has the percentage of oil in the crop of the low-oil side approached that of the high-oil side. In 1898 the average difference in oil content in the corn resulting from the two kinds of seed was 1.11 percent, in 1899 it was 1.35 percent and in 1900 it was 1.97 percent.

From the mixed-oil plot of 1899 there were taken besides these composite samples 85 pairs of individual ears in which each pair consists of one ear produced from a high-oil seed kernel and one from a low-oil kernel, both ears from plants growing in the same hill. Each of these individual ears was sampled and analyzed and these results are given in Table 103 of the appendix.

The average of all of the individual ears from high-oil seed is 5.22 percent and from low-oil seed it is 3.82 percent. But the point of most interest, perhaps, in connection with this table is the regularity with which the oil content of the crop responds to that of the seed planted, for among the 85 pairs there are only four cases in which the oil in the ear, resulting from low-oil seed happens to surpass in percentage that from the high-oil seed.

The results of these three years' experiments with the mixed-oil plot are all in accordance and they establish beyond dispute the possibility of influencing the oil content of corn by the selection of the seed, showing conclusively that heredity has been responsible for the results obtained quite independent of soil, climatic or cultural conditions.

SECONDARY EFFECTS PRODUCED BY SELECTION TO CHANGE THE COMPOSITION OF THE GRAIN

As is always the case in investigations of this sort, the work had not proceeded far before a multitude of interesting side questions arose, inviting investigation in all directions from the main issue. What secondary effects are produced by this intense selection for these special chemical characteristics? What, for example, is the effect of changing the proportion of protein in the grain upon the other constituents? How is the composition of other parts of the plant affected? What influence has it upon the physical type of the kernel and of the ear? And, what is of especially practical importance, how is the yield affected?

Having established the possibility of influencing the composition of the kernel in this way by several years of breeding and after having actually produced the different kinds of corn to work with, it became possible to take up the study of some of these important secondary effects. The results of the investigation of some of these questions are given in the following pages.

EFFECT ON THE COMPOSITION OF OTHER PARTS OF THE PLANT

After the breeding plots had been under way for five years and marked changes had been produced, a study was begun to ascertain how the composition of other parts of the plant was being affected by altering that of the grain.

Beginning in 1903, there have been collected every year at harvest time representative plants from each of the four "Illinois" breeding plots. These plants were divided in the following manner into three parts, namely, upper-stalk, lower-stalk, and leaves. The leaves were first stripped off from the stalks and these, including the husks, constituted the sample designated here as "leaves." Then at the joint where the ear was borne, the stalk was divided and the part below this point comprised the sample called "lower-stalk," and all above including the tassel, made up the sample designated as "upper-stalk."

It may be observed that the condition of these samples is just as it would be in the ordinary handling of corn stover on the farm. It was cured in the field in the ordinary manner, the stalks having lost some parts of the leaves and tassels. Then this rather arbitrary division into parts follows somewhat in the natural way in which the stover is eaten by animals as fed entire without cutting or shredding. The leaves and husks are entirely consumed and usually a portion at least of the upper stalk is eaten. If any is refused, it is the coarser part of the stalk corresponding somewhat to

our sample of "lower-stalk." With this practical bearing in mind, there is lent something of an added interest to the analyses.

The results of the analyses of these samples are brought together in the tables that follow. For convenient comparison each constituent is considered by itself in a table showing the percentages found in the several parts of the plant in the different strains each season.

In the first two years of the work these samples were taken from every individual breeding row in the four plots so that the results shown here really represent averages of several hundred analyses, but these data form such a mass of material that lack of space forbids presenting them here in detail.

EFFECT ON THE ASH CONTENT

We will consider first the effect produced by the breeding upon the ash content as shown in the following table:

TABLE 7.—ASH CONTENT IN DIFFERENT PARTS OF PLANT

Year.	Strain.	Upper-stalk.	Lower-stalk	Leaves.	Grain.
1902	High-Protein.....	5.25	4.08	8.21	1.57
	Low-Protein	5.82	5.09	8.64	1.45
	High-Oil	5.65	4.89	7.59	1.54
	Low-Oil.....	4.91	3.72	7.11	1.42
1903	High-Protein.....	5.23	4.52	9.66	1.52
	Low-Protein.....	4.86	4.28	7.98	1.34
	High-Oil.....	5.20	3.98	8.23	1.47
	Low-Oil.....	4.75	4.27	7.27	1.47
1904	High-Protein.....	4.38	3.95	6.56	1.60
	Low-Protein.....	5.14	4.57	7.51	1.41
	High-Oil.....	5.05	5.80	7.66	1.56
	Low-Oil.....	5.59	5.53	8.12	1.43
1905	High-Protein.....	4 30	4.02	6.52	1.54
	Low-Protein.....	5.00	4.61	7.47	1.50
	High-Oil.....	5.26	5.92	8.06	1.58
	Low-Oil.....	5.69	5.47	8.34	1.28
1906	High-Protein.....	4.77	4.93	9.08	1.48
	Low-Protein.....	4.28	4.15	8.85	1.41
	High-Oil.....	5.05	5.61	7.72	1.64
	Low-Oil.....	5.67	4.84	7.01	1.46

Comparing the percentages of ash in the high-protein and low-protein strains in the upper-stalk, there is no regularity apparent. In two of the seasons the percentage was greater in the high-protein plot and in the three other seasons it was smaller. The lower-stalk varies in the different seasons in accordance with the

upper-stalk, and the same is true of the leaves. In the grain the differences are very slight but they show every season a little more ash in the high-protein corn.

Comparing the samples of the various parts from the high-oil and low-oil strains, we find no regularly concordant variations except in the case of the grain where usually the percentage of ash has been a trifle higher in the high-oil than in the low-oil corn. In regard to the distribution of the ash over the plant as a whole we find, as we should expect in accordance with what is generally observed in plant studies of this nature, the lowest proportion of ash in the seed and the highest in the leaves where it amounts sometimes to almost one-tenth of the dry substance.

EFFECT ON THE PROTEIN CONTENT

It is especially interesting to note how the change in the proportion of protein in the grain has affected this constituent in other parts of the plant. For example, does the increase of protein in the kernel mean an increase of this substance in the other organs of the plant, or is this higher content in the kernel the result of an accumulation produced at the expense of other parts?

Table 8 shows the results of the protein determinations in the various parts of the plant.

TABLE 8.—PROTEIN CONTENT IN DIFFERENT PARTS OF PLANT
(Protein derived by multiplying the nitrogen content by the factor 6.25)

Year.	Strain.	Upper-stalk.	Lower-stalk	Leaves.	Grain.
1902	High-Protein.....	3.31	3.28	5.00	12.34
	Low Protein.....	2.90	3.21	4.99	8.22
	High-Oil.....	3.70	4.72	5.13	10.83
	Low-Oil.....	2.78	2 83	4.86	9.31
19 3	High-Protein.....	4.00	3.20	4.92	13.04
	Low-Protein.....	3.80	4.26	5 28	8.62
	High-Oil.....	3.20	3.28	5.04	11.04
	Low-Oil.....	3.50	3.58	5.04	10.22
1904	High-Protein.....	6.52	5.68	5.34	15.03
	Low-Protein.....	3.06	3.46	4.77	9.27
	High-Oil.....	4.53	4.08	4.86	12.29
	Low-Oil.....	4.00	4.94	5.10	10.88
1905	High-Protein.....	6.13	6.03	6.46	14.72
	Low-Protein.....	3.59	4.59	5.81	8.57
	High-Oil.....	4.38	6.32	6.42	12.12
	Low-Oil.....	4.41	4.09	5.74	9.86
1906	High-Protein.....	5.99	4.94	5.27	14 26
	Low-Protein...	5.61	6.48	7.13	8.64
	High-Oil.....	5.38	6.56	5.57	11.81
	Low-Oil.....	4.37	4.37	5.03	10.54

Upon comparing the protein content of the upper-stalk samples we find that the percentage has always been greater in the high-protein plot varying in the different seasons, from only a slight difference to over double the amount.

The lower-stalk follows the upper-stalk in this respect in three of the seasons but in the other two years the protein runs higher in the low-protein strain. The leaves agree quite closely in every case with the lower-stalk.

The wide differences in the protein content of the grain are, of course, the direct result of the selection which have already been considered so that we need not discuss them further in this connection.

Turning now to the oil breeding, there seems to be a lack of any significant regularity in the parts of the stover. In the upper-stalk the percentage of protein runs higher three out of the five seasons in the high-oil strain. In the lower-stalk it is three times out of the five higher in the high-oil strain but corresponding only three times with the upper-stalk. The leaves correspond with the lower-stalk in this comparison.

But a very marked correlation appears in the grain where there has been every year a notable increase in protein in the high-oil strain over that of the low-oil. This is indeed significant and is of such interest that it will be discussed more fully later on.

Regarding the general distribution of the protein in the plant, the data show; that in the other parts, the proportion of protein is never as high as it is in the grain; that among the other parts, the leaves have averaged somewhat higher than the stalks although this condition has not been constant in every year; that, as between the upper and lower portions of the stalk no regular difference can be established.

EFFECT ON THE CRUDE FAT CONTENT. (Ether Extract.)

It will be noticed that the term "crude fat" is used here for designating this determination rather than "oil" as has been used in the rest of this work in which only the kernels were concerned. It should be considered that while in the kernels the substance extracted by ether is practically all oil, in the stalk and leaves it consists to a considerable extent of other constituents besides true fats, or oil, such as coloring matters, waxes, organic acids, etc. On this account these results of the ether extraction are not to be taken as necessarily explicitly expressing the relations of the amount of oil or fat in the various organs of the plant to that of the kernels. However in the chemical analyses of food stuffs, the ether extraction is the best practical method that we have at present of classify-

ing these substances, and in view of the fact that it is usually made and reported in fodder analyses this determination was made in this study with the idea that the information would be of interest and might prove suggestive. The results are given in Table 9.

TABLE 9.—ETHER EXTRACT IN DIFFERENT PARTS OF PLANT

Year.	Strain.	Upper-stalk.	Lower-stalk	Leaves.	Grain.
1902	High-Protein.....	0.98	1.31	1.02	4.85
	Low-Protein.....	0.82	0.95	1.02	4.15
	High-Oil.....	1.08	1.27	0.99	6.41
	Low-Oil.....	0.87	1.21	1.02	3.02
1903	High-Protein.....	0.92	1.42	1.04	4 83
	Low-Protein	0.77	0.88	0.90	4.08
	High-Oil.....	0.69	0.86	0.98	6.50
	Low-Oil.....	1.18	0.98	0.98	2.97
1904	High-Protein.....	0.77	1.23	1.16	5 07
	Low-Protein	0.78	0.81	1.00	4.17
	High-Oil.....	0 67	0.87	1.10	6.97
	Low-Oil.....	0.69	0.90	0.98	2.89
1905	High-Protein.....	0.95	1.20	1.21	5.04
	Low-Protein	0.88	0.95	1.28	3.85
	High-Oil.....	0.82	1.00	1.24	7.29
	Low-Oil.....	0.72	0.82	1.09	2.58
1906	High-Protein.....	1.02	1.69	1.25	5.28
	Low-Protein	1.62	1.89	1.46	3.86
	High-Oil.....	1.07	2.05	1.32	7.37
	Low-Oil.....	1.29	1.46	1 23	2.66

The proportion of ether-extract in the stalks and leaves is not very large ranging mostly around one percent and there are no apparent relations among these results that would indicate any significant influence of the selections either in the protein or in the oil breeding.

In the case of the grain, however, there is an interesting correlation manifested. We have already seen how the protein content of the grain is influenced by the oil selection, and, just as the protein rises and falls with the oil content, so here the oil follows the protein selections, and in every season there is a decided increase of oil in the high-protein strain over that of the low-protein.

The figures show in regard to the relative proportions of ether-extract in the different parts of the plant, that the crude fat in other parts scarcely ever approaches in percentage the oil in the kernel and also that it is generally greater in the lower-stalk and leaves than in the upper-stalk.

EFFECT ON THE PHOSPHORUS CONTENT

On account of their especial bearing upon questions pertaining to soil fertility a knowledge of the phosphorus and potassium contents in these different strains of corn is of interest. Accordingly determinations of these two elements in the samples of the different parts of the plants have been made since 1903. The percentages are given in Tables 10 and 11 being expressed in terms of the elementary substances.

TABLE 10.—PHOSPHORUS CONTENT IN DIFFERENT PARTS OF PLANT

Year.	Strain.	Upper-stalk.	Lower-stalk	Leaves.	Grain.
1903	High-Protein.....	0.19	0.19	0.15	0.36
	Low-Protein.....	0.12	0.10	0 14	0.30
	High-Oil.....	0.10	0 08	0.10	0.34
	Low-Oil.....	0.10	0.09	0.13	0.31
1904	High-Protein.....	0.26	0.24	0.18	0.38
	Low-Protein.....	0.14	0.10	0.12	0.33
	High-Oil.....	0.21	0.12	0.16	0.38
	Low-Oil.....	0.17	0.17	0.18	0.35
1905	High-Protein.....	0.26	0.22	0.18	0.32
	Low-Protein.....	0.12	0 09	0.12	0.30
	High-Oil.....	0.18	0.11	0.12	0.34
	Low-Oil.....	0 17	0.14	0.17	0.25
1906	High-Protein.....	0 28	0.32	0.21	0.34
	Low-Protein.....	0.29	0.21	0.24	0.30
	High-Oil.....	0.25	0.22	0.19	0.35
	Low-Oil.....	0.19	0.14	0.15	0.31

Comparing the high-protein and low-protein strains it is interesting to note that with only the exception of the upper-stalk and leaves in 1906, the phosphorus content is always somewhat higher in the samples representing the high-protein plot both in stover and grain.

In the breeding for high and low-oil, however, such a correlation does not appear in the stover but in the grain we find regularly a higher phosphorus content in the high-oil corn. Taking the plant as a whole the grain is decidedly the richest part in phosphorus thus conforming to what has been generally observed.

EFFECT ON THE POTASSIUM CONTENT

Comparing the high-protein and low-protein plots the different parts of the stover show agreement in three out of the four years in being somewhat richer in potassium in the low-protein strain. The other season all parts were richer in this element, in the high-protein strain.

TABLE II.—POTASSIUM CONTENT IN DIFFERENT PARTS OF PLANT

Year.	Strain.	Upper-stalk.	Lower-stalk	Leaves.	Grain.
1903	High-Protein.....	1.47	1.64	0.90	0.35
	Low-Protein.....	1.52	1.64	0.97	0.32
	High-Oil.....	1.34	1.10	0.76	0.36
	Low-Oil.....	1.33	1.54	1.25	0.36
1904	High-Protein.....	1.07	1.10	1.02	0.37
	Low-Protein.....	1.67	1.67	1 31	0.35
	High-Oil.....	1.63	1.70	1.48	0.39
	Low-Oil.....	1.55	1.74	1.56	0.39
1905	High-Protein.....	1.03	1.07	1.05	0.34
	Low-Protein.....	1.61	1.62	1.35	0.37
	High-Oil.....	1.65	2.36	1.39	0.36
	Low-Oil.....	1.81	2.08	1.60	0.37
1906	High-Protein.....	1.17	1.54	0.88	0.36
	Low-Protein.....	0.89	1.17	0.82	0.40
	High Oil.....	1.59	2.14	1.22	0.39
	Low-Oil.....	1.59	1.79	0.92	0.40

In the grain samples the comparisons show conflicting results but the differences here are so small as to be scarcely significant.

As between the high-oil and low-oil breeding no regularity among the stover samples can be made out. In the grain the percentages are just a trifle greater in the low-oil corn but the differences are too slight to be considered seriously.

These results likewise accord with the usual observance that the stover carries a much larger proportion of potassium than the grain. The stalks and leaves do not vary greatly in this respect.

CONCLUSIONS

The preceding data afford material for numerous other comparisons and a critical study would doubtless reveal many other suggestive facts, but it is our present purpose only to derive as direct an answer as possible to our main question regarding the effect produced upon the composition of the plant as a whole by altering the relative proportions of the constituents of the kernel.

Summarizing the results of this study and putting them into the form of a general statement we may say, that aside from the correlation developed between protein and oil in the grain, there has not been produced any very marked effect. The ash in the grain appears to be influenced very slightly by the protein as well as the oil selection, following these selections in direct correlation. The same is true of the phosphorus content.

Further there is seemingly a tendency toward an increased phosphorus content in the stover resulting from high-protein selection, but this observation needs further confirmation.

CORRELATION BETWEEN PROTEIN AND OIL IN THE KERNEL

At the beginning of the breeding the correlation between the protein and oil content in the kernel was only very slight. The result of the mathematical calculation of this correlation in the original 163 ears from which the first selections were made, as given in Bulletin 87, shows only 3.81 percent of a perfect correlation.

But, although this correlation is insignificant at first, it seems to have advanced with the breeding so that, as we have just observed, after five years it became very prominent both in the protein and in the oil selections.

It is interesting to trace the development of this correlation in the progress of the breeding as may be done in Table 12 in which are given the percentages of oil in the high-protein and low-protein strains each generation excepting the second and third years when these determinations were not made.

TABLE 12.—OIL CONTENT IN HIGH-PROTEIN AND LOW-PROTEIN STRAINS

	Average percent oil.		
Year.	High-protein crop.	Low-protein crop.	Difference.
1897	4.52	4.35	0.17
1898	....	....	....
1899	....	....	....
1900	4.75	4.31	0.44
1901	4.82	4.30	0.52
1902	4.85	4.15	0.70
1903	4.83	4.08	0.75
1904	5.07	4.17	0.90
1905	5.04	3.85	1.19
1906	5.28	3.86	1.42

The last column which shows the difference in oil content each year brings out the principle in a most interesting way. This difference between the two plots begins with a very small figure which gradually increases as the breeding goes on corresponding to the differences in the protein itself, until in the tenth generation this difference becomes so significant as to amount to about one-third of the total quantity of oil.

In like manner the behavior of the protein in the high and low-oil strains is shown in Table 13.

TABLE 13.—PROTEIN CONTENT IN HIGH-OIL AND LOW-OIL STRAINS

Year.	Average percent protein. High-oil crop.	Low-oil crop.	Difference.
1897	10.76	11.03	- 0.27
1898	.....	.....	....
1899	.....	.....	....
1900	10.83	11.00	-0.17
1901	12.32	10.03	2.29
1902	10.83	9.31	1.52
1903	11.04	10.22	0.82
1904	12.29	10.88	1.41
1905	12.12	9.86	2.26
1906	11.81	10.54	1.27

Although the differences in protein content in the high-oil and low-oil plots have not been as regular or constant as in the case of the oil content in the high-protein and low-protein plots, yet the same principle is evident, for, whereas in the earlier years the protein actually averages a little higher in the low-oil strain as indicated in the table by the minus signs, in later generations after the breeding had advanced and greater differences in the oil content had been induced, the correlation appears and remains, although fluctuating in intensity from year to year.

EFFECT ON THE TYPE OF KERNEL

That the selection for certain chemical constituents has a very noticeable effect upon the physical charactertistics of the kernel was observed very early in the work and in Bulletin 55 descriptions with photographs were published showing the possibility of distinguishing between high-protein and low-protein corn as well as between high-oil and low-oil corn by the mechanical structure of the kernel. The matter has been mentioned again in Bulletins 82 and 100, and Bulletin 87, "The Structure of the Corn Kernel and the Composition of its Different Parts," deals especially with this phase of the subject, treating it in considerable detail. Therefore it is not proposed to discuss this matter at length here, but only to call attention briefly to the facts observed in this connection.

Selection for high-protein has developed a type of kernel having a relatively larger proportion of that part characterized by its horny structure, the soft starchy part which immediately surrounds the germ and runs up into the crown of the kernel being less prominent. In the type of kernel resulting from low-protein selection

this condition is reversed and here the soft starchy part predominates. Viewed externally the high-protein kernel has a somewhat glassy appearance while the low-protein presents a milky effect.

Following the fact that about four-fifths of all the oil in the kernel resides within the germ, the selection for high-oil has resulted in a kernel having a relatively large proportion of germ, while the low-oil selection has produced a kernel whose germ occupies a relatively small proportion of the space.

It should be borne in mind that a reduction of the proportion of germ does not necessarily depend altogether upon a decrease in the absolute size, for the same effect would be produced by increasing the size of the endosperm, and in our low-oil strain this is what has really taken place to some extent, so that the selection has resulted in a large broad type of kernel admitting fewer rows on the cob.

The question is often asked as to whether there is any difference apparent in germination on account of this effect upon the size of the germ. In laboratory tests under carefully controlled and comparable conditions a difference in the rate and vigor with which the germination starts off has been observed, the first signs of growth appearing about twenty-four hours earlier in the high-oil corn. This difference, however, becomes less apparent as the development of the young plantlet proceeds and in the field there is as yet no detrimental effect noticeable due to impaired vitality in the seed brought about by the selection for low-oil.

EFFECT ON THE TYPE OF EAR

That the selection in these different directions has likewise had its effect upon the physical characteristics of the ear is clearly shown in Bulletin 119, "Type and Variability in Corn," in which Dean Davenport and Doctor Rietz have made this matter the subject of a special study.

In this investigation ears from each of the four "Illinois" strains from the crops of the ninth and tenth generations were subjected to measurements of their length, circumference, weight, and number of rows of kernels.

The variability of each one of these charactertistics was studied by the statistical method in which are determined mathematical expressions showing the "mean," or average value of the character in question, as well as its tendency to vary from this average, expressed by the "standard deviation" and the "coefficient of variability." Taking from these tabulated results those figures which are of especial concern in this connection, the following interesting facts are brought out.

Selection for high-protein has produced an ear averaging somewhat smaller than the low-protein ear as shown by a comparison of the length, circumference and weight; the number of rows of kernels also averages slightly less on the typical high-protein ear.

Similarly the high-oil selection has resulted in a smaller type of ear than has the low-oil, the length, circumference and weight being less in each case in the high-oil strain. However, in spite of the fact that the typical low-oil ear is the largest of any of the strains, the number of rows of kernels is the least, this being due to the broadening of the kernel as previously explained.

EFFECT ON THE YIELD

One of the first questions to be taken into consideration from the practical standpoint is, of course, the effect that selection for these various characteristics has upon the productiveness.

In this connection it should be borne in mind that during the earlier years of these experiments in the selection of seed no special precaution was taken against in-breeding. If the pedigree lines be traced back in the high-protein plot it will be found that they all converge in a single ear grown in 1901. The low-protein strain as it now exists is the progeny of two of the original ears and the same is true of the low-oil. The high-oil strain traces back to three original ears. Thus the pedigree records show that there must have been a considerable amount of rather close in-breeding which has probably exerted a more or less detrimental effect upon the yield. It was not until the ninth generation that we started our present system of taking seed from detasseled rows only and arranging the planting of the seed ears with reference to their relationship, in order to prevent as far as possible such close in-breeding.

Neither was there in the earlier years of the breeding any selection based upon productiveness other than the choice of the largest, finest seed ears. In the sixth generation a system of rejecting a few of the lowest yielding rows was begun but it was not until the ninth generation that our present system was adopted of selecting one-half of the detasseled rows according to their performance as regards productiveness.

Therefore in speaking of the yielding propensities of these several strains of corn, these handicaps which they have undergone in the breeding should be taken into consideration.

In order to test this matter of yield, seed has been taken every year since the sixth generation from each of the four breeding plots and planted in our variety test plots where they are given conditions of soil and culture as uniform as possible for securing comparable results.

In this variety test there are planted at certain intervals so-called "Standard plots" from one of the best standard varieties of this region the purpose of these being to serve as a check for comparison in different parts of the field. In Table 14 the yield each year in terms of bushels of shelled corn per acre is given for each of the four "Illinois" strains along with that of the standard variety.

TABLE 14.—YIELDS OF "ILLINOIS" STRAINS IN VARIETY TEST PLOTS

Year.	High-protein strain.	Low-protein strain.	High-oil strain.	Low-oil strain.	Standard variety.
1903	27.3	37.7	32.7	41.3	40.9 (Boone Co. White)
1904	32.1	55.5	41.9	40.5	53.7 (" " ")
1905	56.6	60 7	58.4	58.1	68.4 (Silvermine)
1906	65.1	73.2	66.3	83.2	75.7 (") 87.9 (Leaming)

In looking over these results there are some irregularities to be seen and it is still too early to draw final conclusions in all respects. The maximum yield varies among the four strains in the different years. In two of the seasons the low-oil gave the highest yield and in two others the low-protein yielded most.

But the lowest yield has in every season been produced by the high-protein corn and this fact accords with our previous observation regarding the type of ear where we found the typical high-protein ear to be the smallest of all the four strains. So it seems a high-protein content and the highest productivity do not go together.

The formation of protein depends, of course, upon the supply of nitrogen in the soil. In fact the relation is so intimate that it has been observed in experiments that the protein content can be increased in corn by the application of nitrogenous fertilizers. This suggests the possibility of a limitation of growth on ordinary soil due to an extra high nitrogen requirement on the part of the high-protein strain.

If, however, we consider the production of *protein per acre* we will find a very decided gain in the production of protein in the high-protein breeding. For example in 1906 the high-protein strain produced 65.1 bushels per acre and the protein content of the crop that year as we have seen was 14.26 percent. This would yield (reckoning 56 pounds shelled corn per bushel) 520 pounds of

protein per acre. At the same time the low-protein strain produced 73.2 bushels carrying 8.54 percent of protein which would yield 354 pounds. This makes a difference of 166 pounds of protein per acre in favor of the high-protein breeding. This, however, from the practical standpoint, would be an unfair comparison because ordinarily what the farmer has to deal with is corn of ordinary protein content rather than low-protein corn. We have no "Illinois" strain now unaffected by chemical selection with which to make the comparison. But suppose we compare our "Illinois High-Protein" with the standard white variety for this year, that is the "Silvermine," which has had no chemical selection, and assume that it contains the same percentage with which we started the "Illinois" breeding, that is 10.92, which as a matter of fact is not far from the average of ordinary dent corn. Making the computation we find that the 75.7 bushel yield containing 10.92 percent would give us 463 pounds of protein per acre. Based upon this estimate there was a gain this year of 57 pounds of protein per acre by the high-protein breeding and this is of no mean consequence when we consider that this 57 pounds represents about one-eighth of the total quantity of protein produced.

On the whole these results of the yields are quite gratifying when we consider that these "Illinois" strains have maintained their productiveness as well as they have in spite of the intense selection they have undergone for other special characteristics. With the exception of one season, some one of the Illinois strains has even surpassed in yield the supposedly good variety used as a standard. All of this goes to show that intense selection for a special character is not necessarily accompanied by a reduction in yield, this not implying, of course, that selection for yield alone would not make greater progress when unhampered by consideration for other characteristics.

APPENDIX

In connection with this investigation a large amount of experimental data has been collected. For the selection of seed for these four "Illinois" breeding plots there have been analyzed during the ten years 4990 individal ears. Of these, 756 ears have been selected and subjected to performance test in the breeding plots and the records of these tests form a most interesting and instructive series. The importance of placing these data on record by publication rests not alone upon their direct connection with the subject matter in hand. There are many obscure problems in this work of corn breeding of intensely practical significance upon which we may hope to secure light by a study of such heredity records as these, and in the study of the broader problems relating to the general subject of heredity there has been a lack of just such specific statistical data as these analyses afford. Already they have furnished excellent material for some such studies and naturally their value as such will ever increase with their accumulation. Therefore it seems advisable to present the essential detailed data of these experiments, preferably incorporated in systematic arrangement in an appendix where they may be referred to at pleasure, rather than encumbering the text of the bulletin with such a mass of statistical material.

The following tables are so arranged in series that the complete history of each strain of the breeding is shown by itself. For each year there is given a record of the breeding plot in a table showing the analyses of the seed ears planted and of the corresponding crops harvested. Immediately following this table is a second one in which are listed the analyses of all of the ears examined from that breeding plot for the selection of seed ears to be planted in the succeeding year's plot.

By this arrangement it is made possible with the system of "Register Numbers" and "Dam Numbers" previously explained, to readily find the relationships of all the ears ever produced in each of the four strains.

The first table gives the complete analyses of the 163 original ears from which the four strains of corn were started and a column is added to indicate to which of the breeding plots each of the selected ears is assigned. Following this table are given the series of records for the high-protein plot, low-protein plot, high-oil plot and low-oil plot in the order named.

The "Annual Ear No." in these records correspond to the "Corn No." as used in Bulletin 55 and, as previously explained, this is simply a temporary number used while working with the corn for the selection and has no permanent significance, there is no necessity for changing the back records in this respect and so these old numbers are retained. They begin in the first table with No. 76 and run in the order of the rows of the breeding plot, that is in the order of their mother ears or "Dam Numbers."

In the first year usually four ears were analyzed from each plot-row and every fifth number was given to the composite sample representing the row as will be seen in the tables of 1897. In the years following, up to 1903, nine ears were analyzed from each plot-row and every tenth number was given to the corresponding composite sample. In 1903 the new system was adopted in which the "Annual Ear Number" begins with 1 each year and ten ears are anaylzed from each selected plot-row with no provision for composite sample numbers within the series. In 1905 another modification was introduced in which 20 ears instead of 10 are analyzed from each selected plot-row.

In the tables of analyses all ears that have been selected for seed are indicated by their assigned "Register Nos." being placed in the column opposite.

In order to illustrate the working of this system of records let us suppose that it be desired to trace the pedigree record of a given ear. We may take as an example the first ear analyzed from the high-protein plot in 1906 and registered as No. 1102. We see immediately that the "dam" or mother of this ear was No. 1004. By reference to the plot record of the year 1906 we find that the ear with Register No. 1004 had a protein content of 17.39 percent and that its "dam" was No. 914. Turning now to the plot record of the previous year we find that Register No. 914 had 17.73 percent of protein and by the corresponding "Dam No." we are referred to No. 811 of the preceding generation. Following along in this manner through the preceding generations we finally trace the complete maternal pedigree back to the beginning of the breeding. Thus we find the pedigree record with respect to the protein content of this ear registered as No. 1102 to run as follows:

Maternal pedigree record.	Year planted.	Protein, percent.
Register No. 1102	1907	17.13
By Dam No. 1004	1906	17.39
" " " 914	1905	17.73
" " " 811	1904	17.33
" " " 710	1903	14.70
" " " 601	1902	15.00
" " " 507	1901	15.71
" " " 413	1900	14.53
" " " 323	1899	12.45
" " " 207	1898	12.46
" " " 121	1897	12.28

At the end of these four series of the regular plots are Tables 96 to 103 inclusive which contain the records of the mixed-protein and mixed-oil plots.

TABLE 15.—COMPOSITION OF ONE HUNDRED SIXTY-THREE INDIVIDUAL EARS FROM GENERAL CROP OF 1896
